A *geodesic lamination*  $\Lambda$  on a hyperbolic surface  $\Sigma$  is a closed union of disjointly embedded geodesics. One can also define *abstract* 1-dimensional laminations, i.e. spaces which look locally like a product  $\mathbb{R} \times K$  where  $K$  is some locally compact topological space. We will be interested in the case that  $K$  is totally disconnected. We also typically assume that the total space of our lamination  $\Lambda$  is compact. For a geodesic lamination of course, this is implied when  $\Sigma$  is compact.

If  $\Lambda$  is a 1-dimensional (abstract) lamination, we can define an invariant transverse measure  $\mu$  by taking a sequence of segments in leaves of  $\Lambda$  which are longer and longer, and look at the hitting measure on those segments, scaled by the reciprocal of arclength. For  $\Lambda$  compact, some subsequence converges to an invariant transverse measure. The set of invariant transverse measures supported by a given  $\Lambda$  is the cone on a (Choquet) simplex, whose extremal points are the *ergodic* (projective) transverse measures. Any two ergodic measures  $\mu_1, \mu_2$  which are not proportional are mutually singular — i.e. there exists a measurable subset of  $\Lambda$  with full measure with respect to  $\mu_1$  and zero measure with respect to  $\mu_2$ . A lamination which supports only one projective class of invariant transverse measure is said to be *uniquely ergodic*.

A lamination is *minimal* if every leaf is dense. Any compact lamination admits a minimal sublamination, by Zorn's lemma. It is interesting to come up with examples of minimal (1-dimensional) laminations which are not uniquely ergodic. In what follows, we give a very simple example.

Define inductively a string of 1's and 2's by the following procedure:

- (1) Define  $S_1 = 2221$
- (2) For any string  $\sigma$  of 1's and 2's define the *complement* of  $\sigma$ , denoted  $c(\sigma)$ , to be the string obtained from  $\sigma$  by substituting 2 for each 1, and 1 for each 2. E.g.  $c(122122) = 211211$
- (3) For  $n > 1$ , define  $S_n$  to be the string

$$S_n = S_{n-1}c(S_{n-1})c(S_{n-1}) \cdots c(S_{n-1})$$

where there are  $f(n) - 1$  copies of  $c(S_{n-1})$ , and  $f(n)$  is chosen such that  $f(1) = 4$ , and

$$\prod_n \frac{f(n) - 1}{f(n)} = r > 1/2$$

Then  $S_i$  is the initial string of  $S_{i+1}$  for each  $i$ , and the limit  $S_\infty$  has the following properties:

- (1) Any finite string which appears in  $S_\infty$  appears with density bounded below by some positive constant
- (2) The proportion of 2's in  $S_n$  is at least  $r$  for  $n$  odd and at most  $1 - r$  for  $n$  even

Let  $\Sigma$  be a genus 2 surface, obtained as the union of two 1-holed tori  $T_1, T_2$ . Let  $r$  be an infinite geodesic ray in  $\Sigma$  obtained from  $S_\infty$  as a union of loops in the  $T_i$

representing  $(1, 1)$  curves, where the first three loops are in  $T_2$ , then one loop in  $T_1$ , and so on according to the "code"  $S_\infty$ .  $r$  can be pulled tight to a unique geodesic ray, with respect to any hyperbolic structure on  $\Sigma$ .

If  $r$  is not embedded, it lifts to an embedded ray in the unit tangent bundle  $UT\Sigma$ . Let  $\bar{r}$  denote the closure of  $r$  in  $UT\Sigma$ . Then  $\bar{r} \setminus r$  is an abstract 1-dimensional lamination in  $UT\Sigma$ , which we denote by  $\Lambda$ . Property (1) implies that  $\Lambda$  is minimal. Property (2) implies that it contains two sequences of segments whose normalized hitting measures converge to  $\mu_1, \mu_2$  with total mass 1 such that if  $m_1, m_2$  are meridians on  $T_1, T_2$ , respectively, then

$$\mu_1(m_1) \geq r, \mu_1(m_2) \leq (1 - r), \mu_2(m_2) \geq r, \mu_2(m_1) \leq (1 - r)$$

In particular, these measures are not proportional, and  $\Lambda$  is minimal but not uniquely ergodic.
